**Metal-hydrazine complexes as precursors to oxide materials**

**K C PATIL**  
Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

**Abstract.** Metal-hydrazine complexes, \([M(N_2H_4)_nX]^2+ (M = Mn, Fe, Co, Ni, Zn and Cd, n = 2 or 3)\) with different anions like sulphate, sulphite, acetate, formate, oxalate, hydrazinocarboxylate, nitrate and perchlorate have been investigated as precursors to oxide materials. The thermal reactivity of these complexes changes dramatically with the anion, e.g. sulphate, sulphite, acetate and formate complexes decompose; oxalate and hydrazinocarboxylates deflagrate and nitrate and perchlorate complexes detonate. The deflagrating nature of the metal-hydrazine oxalates and hydrazinocarboxylates has been employed in the combustion synthesis of fine particle \(\gamma\)-Fe_2O_3, Fe_3O_4, ferrites and cobaltites at low temperature.

**Keywords.** Metal-hydrazine complexes; precursors to oxide materials.

1. **Introduction**

The chemistry of hydrazine is of interest since it has a potent N–N bond, two free electron pairs and four substitutable H-atoms. The coordination of hydrazine to the metal ion can either be as a unidentate or bridged bidentate ligand. Hydrazine has positive heat of formation \(\Delta H_f = \sim 12 \text{ kcal mol}^{-1}\) and therefore is thermodynamically unstable. Practically, however, it is quite stable and can be handled safely. Hydrazine is susceptible to catalysis and can explode even at room temperature in the presence of rust \((\text{Fe}_2\text{O}_3)\). Thermal reactivity of metal-hydrazine complexes is of interest since the stability of the complexes changes dramatically, depending upon the anion as well as the cation. In this paper, an attempt is made to correlate the reactivity of metal-hydrazine complexes, \([M(N_2H_4)_nX]^2+ (M = Mn, Fe, Co, Ni, Zn and Cd, n = 2 or 3)\) as a function of anions like sulphate, sulphite, acetate, formate, oxalate, hydrazinocarboxylate, nitrate and perchlorate.

2. **Experimental**

2.1 **Preparation of metal-hydrazine complexes, \(M(N_2H_4)_nX_2\)**

The general method of the preparation of metal hydrazine complexes, \(M(N_2H_4)_nX_2 (M = Mn, Fe^*, Co, Ni, Zn and Cd, n = 2 or 3)\), and \(X = \text{acetate, oxalate, formate nitrate or sulphate}\) involves the reaction of an aqueous solution of the corresponding metal salt with alcoholic hydrazine hydrate.

\[
MX_2(\text{aq}) + n \text{N}_2\text{H}_4 \cdot \text{H}_2\text{O} (\text{alcoholic}) \rightarrow M(N_2\text{H}_4)_nX_2 + n\text{H}_2\text{O}.
\]  \(\text{(1)}\)

*Fe complexes are unstable and spontaneously ignite during suction drying.
The complexes can also be prepared by dissolving the metal powders in a solution of ammonium (NH₄⁺) or hydrazinium (N₂H₅⁺) salts in hydrazine hydrate or water,

\[ M^0 + 2\text{NH}_4\text{X} + 2\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O} \rightarrow M(\text{N}_2\text{H}_4)_2X_2 + 2\text{NH}_3 + 2\text{H}_2\text{O} + \text{H}_2, \quad (2) \]

\[ M^0 + 2\text{N}_2\text{H}_4 + \text{H}_2\text{O} \rightarrow M(\text{N}_2\text{H}_4)_2X_2 + \text{H}_2 + \text{H}_2\text{O}. \quad (3) \]

Metal sulphite and metal hydrazinocarboxylate hydrazine complexes were prepared by the reaction of aqueous metal ions with hydrazine hydrate saturated with SO₂ and CO₂, respectively,

\[ M^{2+} + x\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O} + \text{SO}_2 \rightarrow M\text{SO}_3 \cdot x\text{N}_2\text{H}_4 \cdot y\text{H}_2\text{O} + (x - y)\text{H}_2\text{O}, \quad (4) \]

\[ MX_2 + 4\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O} + 2\text{CO}_2 \rightarrow M(\text{N}_2\text{H}_4\text{COO})_2 \cdot (\text{N}_2\text{H}_4)_2 + 4\text{H}_2\text{O} + 2\text{HX}, \quad (5) \]

2.2 Analysis

The metal content in the complexes was determined by EDTA complexometric titrations. Hydrazine content was estimated volumetrically using 0.025 M KIO₃ solution under Andrews conditions (Vogel 1961).

2.3 Physicochemical studies

Infrared spectra of the complexes were recorded as nujol mulls or KBr discs using a Perkin-Elmer 781 spectrophotometer. Simultaneous TG-DTG-DTA of the complexes were recorded using a TGD-5000 RH thermobalance of ULVAC Sinku Riko, Japan. Thermal analysis curves were recorded in air using 4–5 mg samples. The heating rate employed was 10°C/min. Platinum cups were used as sample holders.

The decomposition/combustion residues of the complexes were characterized by x-ray powder diffraction patterns recorded on a Philips PW 1050/70 diffractometer using Cu Kα and Co Kα radiation.

Temperature profile measurements to determine the surface temperatures in the combustion of FeC₂O₄·2N₂H₄ and Fe(N₂H₄COO)$_2$(N₂H₄)$_2$ were carried out using chromel-alumel thermocouple embedded in 1 cm$^3$ pellets. A time-temperature plot was obtained by feeding the output to a strip-chart recorder.

BET surface area of Fe₂O₃ and γ-Fe₂O₃, ferrites and cobaltites were measured by nitrogen adsorption using Micomericity Accusorb 2100 E instrument. Mössbauer spectra of Fe₂O₃ and γ-Fe₂O₃ were recorded at room temperature employing a BCSIL MBS 35 spectrophotometer with a multichannel analyser. Coercivity of γ-Fe₂O₃ was measured using EQ & α vibrating sample magnetometer fitted with bipolar power supply.

3. Results and discussion

Preparation, infrared spectra and thermal analysis of metal-hydrazine complexes [M(N₂H₄)$_2$]$_{2+}$ (M = Mn, Fe, Co, Ni, Zn and Cd) with anions like nitrate, perchlorate and azide (Patil et al 1982b), oxalate (Patil et al 1982a), formate (Ravindranathan and Patil 1983), hydrazinocarboxylate (Ravindranathan and Patil 1985), sulphate (Patil et
Metal-hydrazine complexes

al 1981; Govindarajan et al. 1985), acetate (Mahesh and Patil 1985) and sulphite (Budkuley 1984) have been investigated. The hydrazine molecule is coordinated to the metal as a bridged bidentate ligand in all these complexes except in the case of hydrazinocarboxylates in which it is coordinated to the metal atom as a unidentate ligand. Infrared spectra serve as a fingerprint technique and the presence of unidentate \( \text{N}_2\text{H}_4 \) in \( M(\text{N}_2\text{H}_3\text{COO})_2(\text{N}_2\text{H}_4)_2 \) is indicated by the characteristic N-N stretching frequency of \( \text{N}_2\text{H}_4 \sim 930 \text{ cm}^{-1} \) (Nicholls and Swindells 1968). The x-ray crystal structure of \( \text{Zn}(\text{N}_2\text{H}_3\text{COO})_2(\text{N}_2\text{H}_4)_2 \) has been determined and the structures of Mn, Fe, Co & Ni complexes are reported to be isomorphous (Ferrari et al. 1966). This study supports the presence of unidentate \( \text{N}_2\text{H}_4 \) in these complexes. The presence of bridged bidentate hydrazine in sulphate, sulphite, formate, acetate, nitrate and oxalate complexes has been indicated by the presence of \( v_{N-N} \) of \( \text{N}_2\text{H}_4 \) in the region 960–980 cm\(^{-1}\) (Patil et al. 1981, 1982a, b; Braibanti et al. 1968) and x-ray crystal structure studies (Ferrari et al. 1965). Thermal reactivity of metal-hydrazine complexes has been investigated by TG-DTA studies. Table 1 summarizes the results of the thermal decomposition of metal sulphate, sulphite, formate and acetate hydrazine complexes. All these complexes initially lose hydrazine exothermically leaving behind the respective metal salts which decompose to the corresponding metal oxides at higher temperatures. The oxide formation temperatures are lower compared to those reported for hydrated metal salts. The metal salts formed by the dehydrazination of the complexes are reactive and decompose at lower temperatures. Table 2 summarizes the results of TG-DTA studies of metal nitrate, oxalate and hydrazinocarboxylate hydrazine complexes. All these complexes show single step decomposition in TG giving corresponding metal oxides. The decomposition of nitrate complexes is violent. The oxalate and hydrazinocarboxylate complexes exhibit autocatalytic combustion behaviour, i.e., combustion is self-sustained once initiated.

* All DTA peaks are exothermic; † $M(N_2H_4)_3(\text{NO}_3)_2$.

The decomposition/combustion of these complexes is accompanied by the evolution of large amounts of gases like NH$_3$, H$_2$O, CO$_2$ and N$_2$. The combustion residues thus left behind are fine and porous metal oxides.

Based on the thermal decomposition studies of metal-hydrazine complexes they can be classified into three distinct groups:

1) Complexes which decompose, i.e., lose hydrazine leaving behind corresponding metal salts. e.g. $M(N_2H_4)_2X_2$, where $X$ = sulphate, sulphite, formate and acetate.
2) Complexes which deflagrate, i.e., exhibit self-sustained (controlled) combustion, e.g. $M(N_2H_4)_2C_2O_4$ and $M(N_2H_3COO)_2(N_2H_4)_2$.
3) Complexes which detonate, e.g. $M(N_2H_4)_3(\text{NO}_3)_2$ and $M(N_2H_4)_3(\text{ClO}_4)_2$.

This dramatic change in the reactivity of the metal-hydrazine complexes can thus be attributed to the nature of the anion i.e. inert, reducing or oxidising. The sulphate and acetate anions are quite inert and do not exhibit any deflagration or detonation. Whereas formate and sulphite complexes although lose hydrazine during decomposition, exhibit self-sustained combustion like oxalate and hydrazinocarboxylate complexes. The explosive nature of nitrate and perchlorate complexes can be attributed to the redox reactions of oxidizer-fuel groups in the complexes.

The role of cation (metal) is also quite important since the explosive nature of transition metal perchlorate hydrazine complexes (Friedrich and Vervoort 1926; Maissen and Schwarzenbach 1951) changes to deflagration in the case of magnesium and aluminium perchlorate complexes (Patil et al 1982b). Thus, the highly unstable and explosive nature of $N_2H_4$ can be controlled by suitably complexing it with selective metal ions and anions.

4. Combustion synthesis

The deflagrating nature of metal oxalate and hydrazinocarboxylate hydrazine complexes has been employed in the combustion synthesis of fine particle Fe$_3$O$_4$, γ-Fe$_2$O$_3$, ferrites and cobaltites.
Synthesis of Fe₂O₄

The decomposition/combustion of Fe(N₂H₃COO)₂ (N₂H₄)₂ in vacuum at \( \approx 250°C \) yields finely divided Fe₂O₄. Formation of Fe₂O₄ was confirmed by x-ray powder diffraction pattern of the residue \( (a = 8.46 \text{ Å}) \). The crystallite sizes of Fe₂O₄ calculated from x-ray line broadening are in the range of 170–250 Å. The surface area of Fe₂O₄ is 50 m²/g. The Mossbauer spectrum of Fe₂O₄ shows the expected hyperfine spectra with the central doublet indicating super paramagnetic nature of the particles. The DTA of this fine particle Fe₂O₄ shows two exotherms at 200°C and 630°C corresponding to the oxidation of Fe₂O₄ \( \rightarrow \gamma\text{-Fe}_2\text{O}_3 \) and \( \alpha\text{-Fe}_2\text{O}_3 \) respectively.

Synthesis of \( \gamma\text{-Fe}_2\text{O}_3 \)

The decomposition/combustion of FeC₂O₄ (N₂H₄)₂ in air at \( \approx 200°C \) yields a mixture of \( \gamma \) and \( \alpha\text{-Fe}_2\text{O}_3 \) as evidenced by the x-ray powder diffraction of the combustion residue. However, the decomposition/combustion of Fe(N₂H₃COO)₂ (N₂H₄)₂ in air at \( \approx 200°C \) gave \( \gamma\text{-Fe}_2\text{O}_3 \) only as indicated by the xrd pattern of the combustion residue \( (a = 8.37 \text{ Å}) \). The crystallite sizes of \( \gamma\text{-Fe}_2\text{O}_3 \) are in the range of 170–250 Å and the surface area is 40 m²/g. Mossbauer spectra of \( \gamma\text{-Fe}_2\text{O}_3 \) showed the expected hyperfine split pattern. The hyperfine field calculated from the fitting of the spectrum is 490 kOe and the isomer shift is 0.3435 mm/sec with respect to stainless steel. The coercivity force observed from the B-H curve of \( \gamma\text{-Fe}_2\text{O}_3 \) is 170 oersteds. The DTA of \( \gamma\text{-Fe}_2\text{O}_3 \) showed an exotherm at \( \approx 630°C \) corresponding to the conversion of \( \gamma \rightarrow \alpha\text{-Fe}_2\text{O}_3 \).

Temperature profile measurement of FeC₂O₄(N₂H₄)₂ (Kishore et al 1986) showed that the maximum temperature attained during the combustion is \( \approx 600°C \) although ignition occurs at \( \sim 200°C \). On the other hand, in the case of Fe(N₂H₃COO)₂ (N₂H₄)₂ combustion the maximum temperature attained was only 425°C. This difference in the exothermicity of the combustion of FeC₂O₄ (N₂H₄)₂ and Fe(N₂H₃COO)₂ (N₂H₄)₂ is probably responsible for the formation of a mixture of \( \gamma \), \( \alpha\text{-Fe}_2\text{O}_3 \) in the former and exclusively \( \gamma\text{-Fe}_2\text{O}_3 \) in the latter. It is well known that \( \gamma\text{-Fe}_2\text{O}_3 \) is converted to \( \alpha\text{-Fe}_2\text{O}_3 \) at \( \approx 600°C \).

Synthesis of ferrites

The preparation of spinel ferrites by the decomposition/combustion of mixed metal oxalate hydrazinates, MFe₂(C₂O₄)₃ (N₂H₄)₆ where M = Mn, Fe, Co, Ni and Zn at low temperatures has been reported (Gajapathy and Patil 1983).

Ultrafine ferrite powders have been prepared by the decomposition/combustion of solid solution precursors of the type M₁/₃Fe₂/₃(N₂H₃COO)₂ (N₂H₄)₂, where M = Mg, Mn, Co, Ni and Zn. These precursors decompose at lower temperatures (125–150°C) with the evolution of large amounts of gases like NH₃, H₂O, CO₂ and N₂ to yield corresponding ferrites. Formation of ferrites was confirmed by their characteristic xrd patterns. The crystallite sizes of the ferrites calculated from the x-ray line broadening are in the range of 130–250 Å. The surface area of the ferrites range from 75–120 m²/g.

Synthesis of cobaltites

The preparation of MgCo₂O₄ and NiCo₂O₄ by the decomposition/combustion of
MgCo$_2$(C$_2$O$_4$)$_3$·5N$_2$H$_4$ and NiCo$_2$(C$_2$O$_4$)$_3$·6N$_2$H$_4$ has been reported (Patil et al. 1983). The decomposition/combustion of solid solution precursors of the type, $M_{1/3}$Co$_{2/3}$(N$_2$H$_4$)$_2$(C$_2$O$_4$)$_2$, where $M$ = Mg, Mn, Fe, Ni and Zn yield fine particle cobaltites, MCo$_2$O$_4$ at low temperatures (200-400°C). Further work is in progress on the characterization of these cobaltites.
